Supercomplex

A B S T R A C T
The five complexes (complexes I–V) of the oxidative phosphorylation (OXPHOS) system of mitochondria can be extracted in the form of active supercomplexes. Single-particle electron microscopy has provided 2D and 3D data describing the interaction between complexes I and II, among I, III and IV and in a dimeric form of complex V, between two ATP synthase monomers. The stable interactions are called supercomplexes which also form higher-ordered oligomers. Cryo-electron tomography provides new insights on how these supercomplexes are arranged within intact mitochondria. The structure and function of OXPHOS supercomplexes are discussed.

1. Introduction
Mitochondria are intracellular organelles which accommodate in their inner or cristae membrane large numbers of five oxidative phosphorylation complexes (complexes I–V). The complexes I to IV are oxidoreductases which, with the exception of complex II, couple electron transport with translocation of protons across the inner mitochondrial membrane (Fig. 1). The generated proton motive force is used by ATP synthase (complex V) for ATP synthesis from ADP and phosphate. Complex I or NADH dehydrogenase is the first and major entrance point of electrons to the respiratory chain. It transfers electrons from NADH molecules to a lipophilic quinone designated ubiquinone. Complex II or succinate dehydrogenase transmits electrons from succinate to ubiquinone and directly connects the citric acid cycle to the respiratory chain. From the reduced ubiquinone electrons can be transferred to complex III or cytochrome c reductase which exists in the membrane as a functional dimer. The small protein cytochrome c mediates electron transfer from cytochrome c reductase to cytochrome c oxidase (complex IV). Finally, electrons are transferred to molecular oxygen which is reduced to water.

The ideas about the overall organization of these five complexes, which together form the oxidative phosphorylation (OXPHOS) system, have been changing with time. A so-called “fluid-state model” is supported by the finding that all individual protein complexes of the OXPHOS system can be purified to homogeneity in an enzymatically active form and by lipid dilution experiments (reviewed in [1,2]). It postulates that the respiratory chain complexes freely diffuse in membrane and that the electron transfer is based on random collisions of the single complexes.

The fluid-state model is challenged by a “solid-state model” which proposes stable interactions between the OXPHOS complexes within entities named supercomplexes. This model is now supported by a wide range of experimental findings: 1. Supercomplexes can be resolved by blue native polyacrylamide gel electrophoresis (BN-PAGE) [3,4]. 2. Supercomplexes are active as shown by in-gel activity measurements within blue native gels [3,5]. 3. Electron microscopy (EM) structures revealed defined interactions of OXPHOS complexes within the isolated respiratory supercomplexes [6–10]. 4. Flux control experiments [11,12] confirm that the respiratory chain operates as one functional unit. 5. Point mutations in genes encoding one of the subunits of one OXPHOS complex affect the stability of another complex. Thus, complex III is required to maintain complex I in mouse and human cultured cells mitochondria [13]. Complex IV is necessary for the assembly or stability of complex I in mouse fibroblasts [14]. 6. Oxygen uptake by isolated mitochondria of potato correlates with the abundance of supercomplexes [5]. 7. Some supercomplexes need cardiolipin for their formation [15,16]. Until some years ago, the fluid-state model was widely accepted in the field of bioenergetics. The newest edition of the Lehninger textbook is the first general textbook that presents a section on OXPHOS supercomplexes [17].

In many organisms the complexes I, III and IV were found to associate into specific supercomplexes (reviewed in [18]). Only complex II seems not to form part of any respiratory chain supercomplexes. The possible explanation for the singular state of complex II is that it is also involved in the citric acid cycle. However, a recent publication on the OXPHOS system of mouse mitochondria also...
reported detection of complex II containing supercomplexes by BN-PAGE [19]. The I+III₂+IV₁–₂ supercomplex is called respirasome because it can autonomously carry out respiration in the presence of ubiquinone and cytochrome c. Respiratory supercomplexes are believed to co-exist in the membrane with single OXPHOS complexes. In this review we discuss the structure and function of the various types of supercomplexes within the mitochondrial membrane. In a few cases it appears that supercomplexes further organize into larger structures called strings. The clearest example is the ATP synthase complex (complex V), which assembles into long oligomeric chains [20–23].

2. Respiratory supercomplexes

High-resolution crystal structures are available for most OXPHOS complexes [24]. Only complex I, which by far is the largest complex of the respiratory chain, has not been crystallized up to now. It has an unique L-like shape which results from the orthogonal association of its two arms, the matrix-exposed “peripheral arm” and the so-called “membrane arm” [25,26]. However, the overall shape varies in different organisms as revealed by electron microscopy. For instance, plant complex I has a second matrix-exposed domain which is attached to the membrane arm at a central position and which includes carbonic anhydrases [27–29]. Furthermore, complex I of Yarrowia lipolytica has an unknown protrusion at the tip of the membrane arm of complex I [26] and complex I from beef an additional density at the membrane arm tip on its matrix-exposed side [18]. The structure of the peripheral arm of complex I from the archaebacterium Thermus thermophilus was recently resolved by X-ray crystallography. Positions of eight subunits and all redox centers of the enzyme were determined, including nine iron sulphur centres [30]. There is much less known about the membrane arm. The main known function of the hydrophobic part is proton translocation [31], but the precise functions of the membrane domain and the coupling mechanism are not yet solved because of lack of high-resolution structural data. However, the projection map at 8 Å resolution of complex I from E. coli obtained by electron microscopy [32] indicates the presence of about 60 transmembrane α-helices within one membrane domain. A binding site and access channel for quinone is predicted to be at the interface with the peripheral arm. The location of subunits NuoL and NuoM at substantial distance from the peripheral arm, which contains all the redox centers of the complex, indicates that conformational changes likely play a role in the mechanism of coupling between electron transfer and proton pumping.

Complex I can form a stable association with the complex III dimer of the respiratory chain [3,4]. An investigation by single-particle EM revealed the lateral association of dimeric complex III with the tip of the membrane part of complex I in Arabidopsis [6], Zea mays [28]; see Fig. 2E) and potato [29]. The top-view projection maps of this plant supercomplex all are similar, although in potato it appears that the angle between complex I and III is variable [32]. In the bovine I + III₂ supercomplex the association of the complexes I and III₂ is about the same (Fig. 2F), but particles in the top-view position are extremely rare, in contrast to the side views (Fig. 2B).

Complex III₂ can associate with one or up to four copies of complex IV as it was described for potato [23], spinach [34], Asparagus [35] and beef [3]. The first detailed structure of a mitochondrial supercomplex was obtained for the III₂+IV₁–₂ supercomplex of Saccharomyces cerevisiae [10]. It could be determined because of its high stability in yeast and for the reason that this organism lacks complex I, which can associate to complex III as well, as described above. The supercomplex appeared in different positions and this allowed generating a pseudo-atomic 3D model which shows that monomeric cytochrome c oxidase complexes are attached to dimeric complex III in two alternate sides with their convex sides facing the complex III₂. This is the opposite to the side involved in the formation of complex IV dimers as described by X-ray crystallography. Association of the complexes III and IV depends on the presence of cardiolipin within the inner mitochondrial membrane [15,16]. In bovine mitochondria complex I (Fig. 2A) binds to complexes III₂ and IV [18]. These supercomplexes represent the largest form of OXPHOS units and are also termed “respirosomes” [3]. Complex III₂ attaches to the complex I at its membrane arm in a region from middle to tip (Fig. 2B) in a similar way like previously described for the I + III₂ supercomplex of Arabidopsis [6]. Bovine complex IV seems to be attached to the tip of complex I (Fig. 2C).

To get a closer look to the composition of the respirasome we produced 2D cryo-EM data on the isolated bovine I + III₂+IV supercomplex on carbon support films (Fig. 2I). In contrast to negative stain freezing in an amorphous ice layer preserves the protein in native water-like environment and does not introduce any artifacts which can occur during chemical fixation with salts of heavy metals followed by air-drying. Additionally, cryo-EM allows to see internal details of the object whereas the negative stain reflects only a contour. Remarkably, freezing of the bovine respirasome provoked slightly different orientation of the complex on the carbon support film. The newly obtained projection map at 24 Å resolution (Fig. 2I) resembles the 2D negatively stained projection map of I + III₂ supercomplex from Arabidopsis and Zea mays (Fig. 2E). A low resolution 3D model of complex I [26] together with the crystal structures available for complexes III and IV are useful to understand
the respirasome architecture. We can precisely assign the positions of complexes III\textsubscript{2} (Fig. 2J, in green) and I (Fig. 2J, in yellow) within the revealed structure and deduce the same overall association of complexes I and III\textsubscript{2} as in the plant supercomplex (Fig. 2H). The small additional density at the tip of complex I and next to the complex III\textsubscript{2} should represent a complex IV monomer. The rotational orientation of complex IV remains unclear and requires further investigation.

Both the 3D model of complex I [26] and the 2D cryo-EM projection map of the membrane arm of complex I [32] clearly show the curved shape of the membrane-embedded part of complex I. Our 2D projection data of Arabidopsis, potato, maize and bovine complex I show the same structural feature. Importantly, the curved feature of the membrane arm can be used as an indicator for a handedness determination of 3D models. Here we can apologize for a wrong handedness in Dudkina et al. [6], as at that time these data were not available. Because it now appears that there is no difference between the bovine and plant I + III\textsubscript{2} supercomplex, we conclude that complex III is always attached to complex I at its inner curved side. This is contradictory to the proposed 3D model at 32 Å resolution in negative stain of the bovine respirasome [36], where complex III is attached at the outside part of the complex I. Evidently, the 3D density map was not correctly assigned. A closer look to their 3D model viewed from the inner membrane side (IMS) clearly shows the typical curvature of the membrane part of complex I, which was omitted in the assignment of the respirasome.

3. Higher organization levels of respiratory supercomplexes

It now appears that the supercomplex formation is not the highest level of OXPHOS organization. A row-like organization of OXPHOS complexes I, III and IV into respiratory strings has been proposed, based on biochemical evidence. It was suggested that respirasomes are interconnected with III\textsubscript{2} + IV\textsubscript{4} supercomplexes [37]. However, it appears that such transient strings cannot be purified after detergent solubilization which limits structural studies. Hence, the proposed respiratory string was approached by an extensive structural characterization of all its possible breakdown products, which are the various types of supercomplexes. About 400,000 molecular projections of supercomplexes from potato mitochondria were processed.

Fig. 2. Examples of EM projection maps of OXPHOS supercomplexes obtained by negative staining (A, B, C, E, F, G, H) and cryo-EM (I, J) plus modelling. (A–C) Averaged side views of bovine complex I and its supercomplexes. (D) Positions of individual complexes within the I + III\textsubscript{2} + IV supercomplex or respirasome from bovine mitochondria [18]. Yellow: X-ray structure of the hydrophilic domain of complex I from *Thermus thermophilus* [30], green: dimeric bovine cytochrome c reductase (complex III) [52], purple: bovine cytochrome c oxidase (complex IV) [53], (E) Top-view of the I + III\textsubscript{2} supercomplex from maize [28], (F, G) Top-views of I + III\textsubscript{2} supercomplexes with an unknown additional mass from bovine and potato mitochondria, respectively (N.V. Dudkina, R. Kouřil, J.B. Bultema, E.J. Boekema, unpublished data). (H) Assignment of the complexes I and III\textsubscript{2} within the top-view map of I + III\textsubscript{2} supercomplex from maize, as presented in image (E), the complex III dimer is in green in a tilted position; in yellow the 3D EM structure of complex I from Yarrowia lipolytica [26]. (I) Map of the bovine respirasome (N.V. Dudkina, unpublished data). (J) Modelling of the respirasome. In beige the position of the membrane arm of complex I, in green X-ray structure of the bovine dimeric complex III and in purple the position of a complex IV monomer. Scale bar, 10 nm.
by single-particle electron microscopy [29]. Two-dimensional projection maps of at least five different supercomplexes, including I + III₂, III₂ + IV₁, V₂, I + III₂ + IV₁, and I₂ + III₁ supercomplexes in different types of position, were obtained. From these maps the relative position of the individual complexes in the largest unit, the I₂ + II₁ + IV₂ supercomplex, could be determined in a coherent way. The maps also show that the I + III₂ + IV₁ supercomplex, or respirasome, differs from its counterpart in bovine mitochondria. The new structural features allow us to propose a consistent model of the respiratory string for bovine and potato mitochondria, composed of repeating I₂ + III₁ + IV₂ units (Fig. 2I, J), which is in agreement with dimensions observed in former freeze-fracture electron microscopy data [23]. This model modifies and extends the hypothetical scheme presented in [37]. There is, however, some evidence for other types of interactions occurring at low frequencies. We found by classification of all breakdown products from cristae membranes big particles, composed of a I + III₂ supercomplex plus a large additional mass in bovine (Fig. 2F) and potato membranes (Fig. 2G), (N.V. Dudkina, R. Kouil, J.B. Bultema, E.J. Boekema, unpublished data). The composition of the additional mass is unknown, but it appears to be larger than a single copy of complex IV, because these novel particles are larger than the respirasome (Fig. 2L).

Another example of a higher-level organization of supercomplexes, dealing with oligomeric ATP synthase, is discussed in the next section.

4. The dimeric ATP synthase supercomplex and its oligomeric organization

Mitochondrial F₁F₀ ATP synthase is a complex of 600 kDa formed by 15–18 subunits [38,39]. The matrix-exposed water soluble F₁ part is constituted of three α and three β subunits and connected to the membrane part via central and peripheral stalks. The F₀-part is composed of subunits α (Su 6), A6L (Su 8), e, f, g, the central stalk consists of the γ, δ and ε subunits and the peripheral stalk is made from subunits OSPC (Su 5), b, d, F6 (h) [40] (different names of the yeast counterparts in brackets, reviewed in [40]). The yeast protein has two additional, specific subunits i and k. A monomer is active in ATP catalysis and hydrolysis like its counterpart in prokaryotes, but evidence for a dimeric organization of the ATP synthase complex came as a surprise from BN-PAGE work on yeast [41]. The 1200 kDa dimeric complex includes dimer specific subunits e, g and k, which were not detected in monomers. Later, dimers were found in beef, Arabidopsis and several other organisms [3,4]. The dimer specific subunits e and g, as well as the subunits α, β, h and i of the monomer, stabilize the monomer–monomer interface [40]. To date, 2D maps of dimeric ATP synthase are available for bovine [8], the colorless green alga Polythelia [7] and S. cerevisiae [21] obtained by single-particle electron microscopy. In all organisms two monomers associate via the membrane F₀ parts and make an angle, which can be fixed or variable between 35 and 90°. Dimeric ATP synthase from Polythelia seems to be the most stable one and the monomers make one specific angle of 70°, as discussed below (Fig. 4C).

Despite the fact that the ATP synthase dimers were first described in the 1990s [41], older work even hint at a higher type of organization as oligomers. Rows of dimeric ATP synthases were demonstrated in Paramecium mitochondria by rapid-freeze deep-etch electron microscopy [23]. Additional BN-PAGE evidence of trimeric and tetrameric organizations of mammalian ATP synthases [20] supports the hypothesis of an oligomeric arrangement of ATP synthases in the membrane. Another BN-PAGE work on mammalian enzyme revealed only ATP synthase fragments with an even number of ATP synthases [42]. Ultrasound and negative staining of osmotically shocked Polythelia mitochondria came to the same conclusion [21]. Later, atomic force microscopy on isolated inner membranes from baker's yeast revealed rows of dimeric ATP synthases, although remarkably no curvature of the membrane was shown at all, likely due to flattening of the membrane on the substrate [43]. This is in contrast with the fact that isolated bakers' yeast ATP synthase dimers make a large angle [21]. Recently cryo-electron tomography (cryo-ET) data on bovine and rat fragmented mitochondria demonstrated long rows of dimers located at locally curved cristae membranes [22]. Averaging also revealed larger angles between monomers than reported for isolated bovine dimeric ATP synthase [8]. In another study, dimeric ATP synthase was studied in intact Polythelia mitochondria. Cryo-ET experiments with mitochondria embedded in amorphous ice showed the presence of oligomeric rows of ATP synthases in mitochondrial cristae [44]. Details of the rows were obtained at a resolution of 5.7 nm by averaging subvolumes of tomograms; this shows that the oligomeric chain is composed of repeating dimeric units with a spacing of 12 nm. The monomers make contact via the membrane part and the peripheral stalk (Fig. 4B) and individual dimers resemble very well the projection maps of isolated dimers in negative stain (Fig. 4C) [7] and amorphous ice (Fig. 4E) as can be seen from the connection of the stator to the F₁ headpiece (yellow arrows). The dimer–dimer interface is not yet well understood. The resolution of 5.7 nm for Polythelia appears in the same range as the 5 nm resolution claimed for the ATP synthase oligomers from bovine and rat liver dimers [22]. However, in contrast to the Polythelia data, the F₁ headpieces in the latter work merely look like feature-less spheres. In conclusion, the tomography data convincingly show the oligomeric state of the ATP synthase complex, but are far too low in resolution to reveal subunit interactions. From biochemical experiments it was predicted that subunits e, f, g. Su 8 (A6L), some transmembrane helices of the α-subunit as well as carriers for inorganic phosphate and for ADP/ATP are potential candidates for the oligomerization of ATP synthases [40].

5. Potential functions of OXPHOS supercomplexes

The occurrence of several specific supercomplexes and higher-ordered oligomers must have functional reasons. It was proposed that OXPHOS supercomplexes allow enhancement of the flow of electrons...
between the complexes by reducing the distance of diffusion of the mobile electron carriers ubiquinone and cytochrome c or by substrate channeling between associated OXPHOS complexes [10,45]. A direct role of the I + III2( + IV1,2) supercomplex in ubiquinone-channeling is not clear so far, because the ubiquinone-binding domain of complex I possibly is not in close proximity to the complex I–complex III2 interphase [6]. However, even if direct channeling does not take place, transfer of ubiquinol from complex I to complex III2 still might be facilitated due to reduced diffusion distances. In plants the I + III2 supercomplex might be necessary for the regulation of alternative respiration by reducing access of alternative oxidase to ubiquinol [4]. In yeast formation of the III2+IV1 supercomplex seems to optimize the electron transport between complexes III and IV by a contraction of the cytochrome c movement between these two complexes [10]. The same can be valid for potato mitochondria based on the facts that complexes I, III and IV are rate limiting in flux control experiments and cytochrome c was found in the supercomplex [2]. Meantime, the same experiments did not demonstrate this for bovine heart mitochondria. Finally, supercomplex formation was suggested to be important in preventing excess oxygen radical formation [2].

Besides functional reasons, supercomplex formation is necessary for assembly and stability of its individual components. As an example, complex I is necessary for fully assembled complex III in human patients with mutations in the complex I subunits NDUF52 and NDUF54 [46] and the absence in complex III results in a dramatic loss of complex I in humans [47]. Furthermore, complex IV is required for the assembly of complex I in fibroblasts [14] and complex III2 is essential for the stability of complex I in mouse cells [13]. The need for a higher organization in supercomplexes might be a more general requirement because in Paracoccus denitrificans assembly of respiratory complexes I, III, and IV into the respirasome stabilizes complex I [48].

The occurrence of ATP synthase dimers and oligomers has a special reason. Dimerization leads to a local curvature of the cristae membrane. Ultrastructural studies on yeast null mutants of dimer specific c and g subunits which lack the dimeric state of ATP synthases indicated that their mitochondria exhibit an unusual onion-shape morphology without any membrane foldings [49,50]. This strongly suggests that dimerization of ATP synthases is essential for cristae morphology. A recent study on mammalian mitochondria proved the organization of ATP synthases in long ribbons of dimers. The mitochondrial cristae may act as proton traps and enhance the local proton gradient necessary for ATP synthesis. In this way ATP synthases may optimize their own performance under proton-limited conditions [22].

6. Prospectives

Up to now a large amount of data on the OXPHOS system has been collected with different biochemical and biophysical techniques. Nevertheless, a complete picture of the protein organization in the cristae membrane is not yet available. Much higher resolution structural data on specific supercomplexes are necessary to give a full interpretation at the atomic level of subunit interactions and electron flow. The structural information of the dimeric ATP synthase complex, I + III2 supercomplex and the respirasome should be improved by either X-ray crystallography or single-particle electron microscopy. The organisms discussed above, such as Paromyzella, are obvious candidates to provide the most stable types of supercomplexes.

Despite the fact that the oligomeric organization of ATP synthases has now been proven, the position of the other OXPHOS complexes, in particular the respirasomes, within the cristae membrane is still unclear. According to [22], respirasomes and single respiratory complexes could be located in the less curved regions of the cristae membrane. Another
possibility would be a localization between the rows of ATP synthases. However, available data suggest that likely the amount of respiratory chain complexes is very limited in comparison to ATP synthases and it is difficult to detect them at this resolution. A breakthrough is expected by further application of cryo-electron tomography, as discussed for ATP synthase oligomers (Fig. 4). Electron tomography is an emerging technique, but still limited in resolution. In addition to 3D averaging and classification of individual subvolumes improvement in resolution is expected in the near future by perfecting cryo-electron microscopy hardware and software, and implementing the new generation of direct electron detectors, replacing the currently used inefficient slow-scan CCD cameras.

Finally, our understanding of supercomplex organization will also increase by studying the structural aspects of the many naturally occurring mutants of the OXPHOS system. Since the first report of a complex I deficit related to a human mitochondrial disorder in 1988, many other mitochondrial diseases have been associated to structural and functional defects at the level of this enzyme complex I (see for instance [46,51]).
